Summary

Background: Hyper IgE syndrome (HIES) is a rare primary immunodeficiency disorder characterized by the triad of elevated IgE and eosinophilia, eczema and recurrent skin and pulmonary infections. Mutation in the STAT3 gene accounts for majority of the autosomal dominant and sporadic forms of HIES.

Objective: To report clinical and molecular analyses of patients with Hyper IgE syndrome from a single tertiary care center in India.

Methods: Four patients with suspected HIES were studied. Flowcytometry for T H17 cell numbers and phosphoSTAT3, and STAT3 gene sequencing were performed.

Results: TH17 cells were significantly reduced. Mutations were found in the DNA-binding domain in three and a mutation in the transactivation domain in one patient. One of the mutations detected was a novel mutation (g54792c.1018A>C p.K340Q) in the DNA binding domain.

Mycobacterial infection, which is usually not commonly associated with HIES was found in two of our cases, one with a cutaneous abscess in the shoulder, and the other with BCG site reactivation.

Conclusions: A novel mutation in the STAT3 is reported. Mycobacterial infections can be seen in the spectrum of HIES related infections. (Asian Pac J Allergy Immunol 2014;32:)

Keywords: Hyper-IgE Syndrome, Mycobacterial infection, novel STAT3 mutation, phosphoSTAT3, Th17 cells

Introduction

Davis, Schaller, and Wedgwood first coined the term Job’s syndrome1 for this entity in 1966. They reported two red-haired, fair-skinned girls with frequent sinopulmonary infections, severe dermatitis, and recurrent staphylococcal cold abscesses in the skin. The syndrome was further defined and clarified by Buckley et al in 1972, who noted similar manifestations in two boys with severe dermatitis, characteristic facies, and elevated IgE levels, leading to the term Buckley’s syndrome.2 The pathogenesis of Hyper IgE Syndrome (HIES) remained unknown till 2007 when mutations in STAT3 (Signal Transducer and Activator of Transcription 3) were documented in patients with autosomal dominant (AD) and sporadic forms of HIES by two investigating groups simultaneously.3,4 HIES is clinically a triad of high serum levels of IgE (>2000 IU/ml), recurring staphylococcal skin abscesses, and pneumonia with pneumatocele formation. Chronic eczematoid dermatitis, coarse facies, mild eosinophilia, and mucocutaneous candidiasis, are variable features. Dental abnormalities (retained primary teeth, non-eruption of permanent teeth, double rows of teeth), anomalies in midline facial development, and skeletal abnormalities (bone fractures, hyperextensible joints, scoliosis) reflect the multisystem nature with the involvement of seemingly unrelated systems and dissociated manifestations. Both autosomal dominant (AD-HIES) and recessive (AR-HIES) modes of inheritance are seen, with skeletal manifestations being a feature of the former, whereas viral infections and neurologic manifestations are a feature of the AR-HIES.
STAT 3 mutations are the predominant cause of sporadic and familial HIES, although other genomic loci may also be involved. STAT3 is involved in the signal transduction of many cytokines, including but not limited to IL-6, IL-10, IL-21, IL-22, and IL-23, and also plays an integral role in wound healing, angiogenesis, cancer, and immunity. STAT3 is implicated in the differentiation of IL-17 producing CD4+ T lymphocytes, important for immunity to extracellular bacterial infections and fungi. STAT3-related HIES have been consistently shown to have impaired development of TH17 cells and IL-17 production and this defect in the STAT3-IL-17 axis have been proposed as a major pathogenic mechanism of the defective immunity against extracellular bacterial pathogens. The other genes that have been implicated in HIES include TYK2 and DOCK8.

Methods

Four cases of STAT-3 related Hyper-IgE Syndrome, from three kindreds, diagnosed at the Postgraduate Institute of Medical Education and Research, Chandigarh, India, were included. Written informed consents were obtained from the patients or their families. The study was approved by the Institute Ethics Committee. The clinical presentation and laboratory findings are summarised in table 1.

**TH17 cell assessment**

PBMCs were isolated with Ficoll-Hypaque density centrifugation (Sigma Aldrich, St Louis, Mo). TH17 cells were identified by means of intracellular staining of CD4+ T cells for the production of IL-17. Briefly, 1×10^6 cells from patients and control subjects were stimulated for 6 hrs with 10 ng/ml phorbol 12-myristate 13-acetate and 1 μg/ml ionomycin (Sigma-Aldrich, St Louis, Mo) in the presence of GolgiPlug (BD Biosciences, San Jose, CA). After cell-surface staining with PerCP-conjugated anti-CD4 (BD Biosciences, San Jose, CA), cells were fixed, permeabilized (Cytofix/Cytoperm, BD Biosciences, San Jose, CA), and stained with Alexa Fluor 647-conjugated mouse anti-tyrosine 705 phosphorylated STAT3 (pY705-STAT3) mAb (BD Biosciences, San Jose, CA). Samples were acquired on FACS ARIA III and results were analyzed using Cell Quest Pro software (BD Biosciences).

**Mutation analysis**

The STAT3 gene was amplified by PCR from genomic DNA (gDNA) using specific oligonucleotide primers. Briefly, gDNA was prepared from venous blood by using the AxyPrep Blood Genomic DNA Miniprep Kit (Axygen BioSciences, Union City, USA). The amplified gene fragments were sequenced from Eurofins Genomics India Pvt Ltd, Bangalore, using the ABI Big Dye Terminator mix (Applied Biosystem, Carlsbad CA) and analyzed with a 3730xl DNA Analyzer, BDT version 3.1 (Applied Biosystems, Carlsbad CA). The sequencing data were analysed using Codon Code Aligner software. A polymorphism Phenotyping program (PolyPhen, [http://genetics.bwh.harvard.edu/pph](http://genetics.bwh.harvard.edu/pph)) and a SIFT (Sorting Intolerant from Tolerant) program were used to predict the effect of the identified STAT3 mutations. This program predicts whether an amino acid substitution affects protein function, based on sequence homology and the physical properties of amino acids.

Results

**Serum IgE levels and absolute eosinophil counts (AEC):**

Three of the four patients showed IgE levels above 2000 IU/ml at presentation (45,935 IU/ml, 22,400 IU/ml, and 4300 IU/ml). One patient (case 3) had a lower initial serum IgE of 822 IU/ml but this subsequently increased to 54,000 IU/ml. The AECs were 295, 856, 603, and 948/mm³ respectively (normal range 50-350/mm³).

Figure 1. (a) Case 1 showing coarse facial features with broad forehead, bushy eyebrows and bulbous nose. (b) The patient, in his childhood photograph showed the presence of the facial features. (c) Facial appearance of the 14 months old child, elder sibling of case 2 with widely spaced eyebrows, wide forehead, and a broad nasal bridge. This child expired before he could be investigated. Mutation studies could not be done, and hence are not included in this case series (d) Case 3, showing relatively milder facial features. (e) Case 4, despite a cushingoid appearance because of therapy with steroids, a gradual coarsening of facial features could be appreciated. (f) Ulcers in the tongue and lower lip (arrows) with punched out distortion of the right lateral border of the tongue in case 4, photographed at a stage when the acute lesions were healing after steroids. (g) Family trees representing the three kindred.
**Percentage of TH17 cells**

All the four cases showed a reduction in the TH17 cell numbers, which ranged from 0.09 to 0.2% (0.2, 0.09, 0.1 and 0.2% respectively). The data are represented in Table 1 and Figure 3.

**Evaluation of Phospho-STAT3 status**

Flowcytometry for pSTAT3 could be performed in two patients (case 1 and case 4). A normal pSTAT3 was observed in case 1 with 46.9% of the cells showing pSTAT3 against a control of 52.4% respectively, while in case 4, only 2.5% of the cells showed phosphorylation. The test could not be performed in cases 2 and 3. Figure 3 shows pSTAT3 activity in terms of change in mean fluorescence intensity (MFI) between the stimulated and unstimulated cells of cases 1 and 4.

**Mutation analysis:**

The various mutations observed are shown in Table 2. Case 1 showed an A to C transversion in exon 10 at the nucleotide g54792 position (c.1018 A>C), leading to substitution of lysine at amino acid position 340 for glutamine (p.K340Q) in the DNA binding domain (Figure 4a). This mutation was not found in the single nucleotide polymorphism database (dbSNP; www.ncbi.nlm.nih.gov/projects/SNP) and hence is considered to be a novel mutation. The mutation had a SIFT score of 0.01 (damaging) and a polyphen score of 0.99 (damaging). The same mutation was demonstrated in Case 2. One hundred and two alleles from 51 healthy volunteers were sequenced for exon 10, and no mutations were found.

Case 3 showed a G to A transition in exon 13 at nucleotide position g.58854 (c.1145 G>A), leading to substitution of arginine at amino acid position 382 for glutamine (p.R382Q) in the DNA binding domain (Figure 4b). The mutation had a SIFT score of 0.12 (tolerated) and a polyphen score of 1.00 (probably damaging).

Case 4 showed a C to T transition in exon 22 at nucleotide position g.71311 (c.2141 C>T), leading to substitution of threonine at amino acid position 714 for isoleucine (p.T714I) in the transactivation domain (Figure 4c). The mutation had a SIFT score of 0.43 (tolerated) and a polyphen score of 0.99 (probably damaging).

**Discussion**

HIES is a relatively rare disorder and diagnosis requires a high index of clinical suspicion. Though definitive clinical scoring systems have been devised, the diagnosis can be challenging, especially in young children. This is exemplified in case number 4, where the clinician suspected the diagnosis, in spite of a very atypical presentation, based solely on the observation of a gradually coarsening facies over a very short follow-up.
Hyper-IgE Syndrome with a novel STAT3 mutation

Pneumonias in HIES are mainly caused by *Staphylococcus aureus*, *Streptococcus pneumoniae*, or *Haemophilus influenzae*. The pneumatocele that typically follow the resolution of cured bacterial pneumonias are frequently superinfected by *Pseudomonas aeruginosa* and *Aspergillus fumigatus*. Mycobacterial infections, though reported, are not a common feature observed in HIES; however, Case 3 had an abscess in the arm which was positive for Mycobacterium tuberculosis. Case 4 showed BCG site infection. It seems likely that the occurrence of Mycobacterial infections in HIES might not be uncommon in countries where mycobacterium tuberculosis is endemic. BCG vaccination in cases where the diagnosis of HIES is made early enough, should be undertaken cautiously and a drug prophylaxis should be considered.

Mucocutaneous fungal disease can be seen in up to 43%-85% of HIES, including 64% of patients with oral candidiasis during the neonatal period. Along with a low T H17 cell count, HIES can thus have features overlapping with chronic mucocutaneous candidiasis. Patients with HIES however also present with other predominant features, such as eczema, skin abscesses and pneumonias, while isolated significant and destructive mucocutaneous candidiasis is not a common presenting feature. Case 4 in our report presented predominantly with oral and anal ulcerations very early in life, i.e. at two months of age, which prompted the initial diagnosis of neonatal Behcet’s disease. This is a rare presenting feature in HIES.

*DBD- DNA binding domain, TA- Trans-activation domain.
The mutation demonstrated in the first kindred, with a clear cut autosomal dominant phenotype, is a novel mutation and hasn’t yet been reported in literature. The mutations in case 3,4 and case 4 have been previously reported and were sporadic mutations.

Mutations involving the DNA binding domain along with the SH2 domain comprise the mutation hotspots in patients with HIES. STAT3 phosphorylation has been shown to be reduced in SH2 domain mutations, whereas with mutations in the DNA binding domain, STAT3 phosphorylation is often normal. Mutations in the transactivation domain, which primarily affect the phosphorylation site, are likely to affect phosphorylation of STAT3 to a greater extent. Hence, pSTAT3 status in our patients correlated with the mutations.

This is the first single centre based report of STAT3 mutation analysis from the Indian subcontinent. More cases need to be screened on a multi-institutional nation-wide collaborative basis.
